FREEDOM: FAST RECOVERY ENHANCED VR DELIVERY OVER MOBILE NETWORKS

THE COMMONLY USED SYSTEMS

- If we use mobile devices for watching virtual reality content, the images rendering will be performed on a chip which is placed on the headset.
- In the commonly used systems the server sends data to the client and these are shown directly to the user.
- These systems depend on the network and on the preprocessing of data.

FREEDOM (I)

- Freedom gives us the possibility to keep the information on a remote server and we use <u>4G/LTE</u> cellular networks in order to access the information.
- Freedom saves 80\% of bandwidth compared to a classical 360 streaming because Freedom does not send the full panorama and does not perform a <u>prefetching</u> for the unused data.
- Freedom can be used also for gaming (the user can enter data in real time using a connected controller) and for live streaming.

FREEDOM (2)

- As opposed to the other methods the server does not send data directly to the client, but creates Visible Area and Margin frames (<u>VAM</u>) at <u>runtime</u>. A Visible Area and Margin frame contains the pixels around the field of view.
- Using this subset of pixels the device can render images for changing the view in a specified interval. This way, the local rendering can be applied and the frames can be <u>intercalated</u> by <u>applying</u> a fast refresh before the server performs the update.

FREEDOM (3)

- When the user is moving his head the client sends a request to the server for establish a new viewpoint, but until then the client can render locally <u>usind</u> the previous <u>VAM</u> frame.
- When the user is moving his head again, the client cannot render the new viewpoint anymore, but the previous viewpoint is rendered and the new viewpoint will be used when the server will send the new <u>VAM</u> frame.

FREEDOM (4)

- At every step the system will need enough pixels for rendering the viewpoint locally. We must anticipate the next changes of user's view until the server will send a new <u>VAM</u> frame with pixels to the headset (to the client).
- For creating a <u>VAM</u> frame the image <u>coresponding</u> to the current viewpoint is rendered, this image must be scaled, a central area of the image must be cut and this area will be send to the client.

FREEDOM (5)

- People usually move their heads on the horizontal axis or on the vertical axis, almost never the movement will be more complex than this.
- We must anticipate the way that user will move his head because the next viewpoints must be rendered using the auxiliary frame.
- For example, if the user is changing his view continuously to the left, we will not consider the current viewpoint in order to create a new auxiliary frame, we will take a viewpoint which is placed further left than the current viewpoint because we expect that the user will move his head further to the left.

FREEDOM VERSUS FURION (I)

FREEDOM

- The server can send VAM frames and using these frames the client can render locally until the viewpoint is not placed in the current VAM frame area anymore.
- Freedom can handle dynamic games or live streaming.

FURION

- Furion creates a 360 degree view for each potential viewpoint (this is why Freedom is far better than <u>Furion</u> in terms of bandwidth savings).
- <u>Furion</u> does not handle dynamic games or live streaming because the server must render the scene every time in advance (for example, if there is a game with static objects only the scene must be rendered, but <u>Furion</u> does not support the movements of a character which is controlled by the user)

FREEDOM VERSUS FURION (2)

FREEDOM

 For a static scene <u>Furion</u> is more suitable than Freedom because <u>Furion</u> does not need refresh, but Freedom is still doing refresh.

FURION

- If the scene uses only static objects and characters, <u>Furion</u> will not use any bandwidth.
- If the scene uses dynamic objects the movement must be 5 times slower in order to keep the streaming without pauses.

FREEDOM VERSUS CLASSICAL THIN-CLIENT SYSTEM

FREEDOM

- Freedom creates <u>VAM</u> frames and those pixels are used by the client to render locally until the server will send the next <u>VAM</u> frame.
- Refresh frequency 60 Hz
- This latency can be handled because of the locally rendering.

CLASSICAL THIN-CLIENT SYSTEM

- The client receives the virtual reality content from the server and displays it.
- Refresh frequency 90 Hz
- Any kind of latency must be avoided in the communication between server and client.

FREEDOM VERSUS OUTATIME (I)

FREEDOM

 The density of pixels and margin sizes are always the same (this is an advantage of Freedom compared to <u>Outatime</u> because the frames have the same properties).

OUTATIME

 Outatime (a cloud gaming system) uses a clipped cube map, which means that the density of pixels is different.

FREEDOM VERSUS OUTATIME (2)

FREEDOM

 Freedom does not anticipate the character's movement, it only anticipates the user's head movement.

OUTATIME

• The human eye cannot notice a 100 ms delay, which means that Outatime, which is a gaming system, must hide the latency of communication between server and client by anticipating the character's movement.

FLASHBACK (I)

- Flashback avoids the real-time image rendering by keeping in a cache the potential images which can be sent to the client. Flashback and Freedom can both handle static and dynamic scenes.
- If the mobile has a weak <u>GPU</u>, Flashback is better than Freedom because the Flashback's cache can keep an entire virtual reality scene and Freedom relies on a high performance <u>GPU</u>.

FLASHBACK (2)

- Flashback can support dynamic scenes because each object has its own cache. For a dynamic object we keep in the cache its relative distance to the player position and its orientation.
- The latency and the image quality of Flashback are similar to the latency and the image quality of a good gaming desktop.

ANOTHER APPROACH (I)

- Another approach is based on hiding the network latency using the image decomposition and creating a new image. The view is divided into 2 separate views: a primary view and a secondary view. The focus will be on the primary view and the details such as pixels shadows will be ignored.
- The performance of this system is better than the performance of Freedom and the system requirements of this system are lower than the system requirements of Freedom, but Freedom is more accurate than this system.

ANOTHER APPROACH (2)

- In a simple arhitecture the actual image relies on the previous image, but the user cannot see the objects which were occluded in the previous scene. T
- There are 2 cases of occluded objects: 1. An object is between the camera and the other object or 2. The objects are outside the field of view.
- The second problem can be solved by extending the field of view to 180 degrees and the first problem can be solved by showing the <u>occulted</u> objects only for the primary view.

QUICKTIME VR (I)

- QuickTime VR is an image file format which uses 360-degree cylindrical panoramic images.
- When the virtual camera is moving there are 6 degrees of freedom which are divided into 3 categories: 1. The movement on the 3 axis Ox, Oy and Oz, 2. Rotating the camera near the object while keeping the view to the center of the object (the viewpoint has been changed) and 3. Changing the viewpoint and the view (the view direction is not oriented to the center of the object anymore).

QUICKTIME VR (2)

- The panoramas are captured using multiple angles and the objects are captured by moving the camera to different positions, but keeping the viewpoint direction oriented to the center of the object.
- In 1995, the researchers found out how to explore <u>VR</u> objects from various angles using <u>QuickTime</u> and in 2019 they developed a system called Freedom which saves bandwidth by anticipating the user's head movements.
